ABSTRACT

Aims: Posttransplant cardiac complications are well-known adverse events constituting a major cause of morbidity and mortality in patients undergoing liver transplantation regardless of etiology of chronic liver disease. To determine the predictive accuracy of Positron Emission Tomography (PET) stress testing for postoperative ischemic cardiac events in patients undergoing liver transplantation. **Methods:** We evaluated 60-day postoperative cardiac complications for patients who had undergone PET stress testing for preoperative evaluation. **Methods:** Patients with end-stage liver disease (ESLD) who underwent liver transplantation between 2009 and 2015 were reviewed. Patient demographics, risk factors, and short-term postoperative cardiac complications were collected and statistical analysis was performed. **Results:** A total of 31 patients (25 [81%] men and 6 [19%] women) with a mean age at transplantation of 55.3 year (range 38–67) were identified. Cardiac risk factors included diabetes 15 (48%), hypertension 16 (52%), and current/former tobacco use 17 (55%). **Contributing factors to ESLD were**

chronic HCV infection 17 (55%), alcohol abuse 9 (29%), NASH 9 (29%); PSC/cholangiocarcinoma 1 (3%), sarcoidosis 1 (3%), and cryptogenic 1 (3%). Calculated MELD score for patients with preoperative labs ranged from 10.1 to 29.2. All 31 patients had a PET stress testing for preoperative assessment. 29 (93%) had a negative stress test. Post liver transplantation, only 1 (3%) patient had third degree atrioventricular (AV) blocks attributable to ischemia at 60-day follow-up. Other notable postoperative complications include hypotension 5 (16%), acute renal failure 5 (16%), acute pulmonary edema 2 (6%) and congestive heart failure 4 (13%). **Conclusion:** PET stress testing has a high negative predictive value for postoperative acute coronary syndromes in liver transplant patients (Negative Predictive Value (NPV) = 96.5%, 95% confidence interval (CI) 96.22–96.88%).

INTRODUCTION

Ischemic cardiac and neurologic complications remain a major concern for patients undergoing surgery with general anesthesia [1]. Few of ischemic complications include cerebrovascular accidents, myocardial infarction, heart blocks, and postoperative atrial fibrillation [2]. Risk factors that predispose to increased postoperative ischemic complications include: prior history of ischemic heart disease, prior history of stroke or vasculopathy, high-risk surgery – including vascular and intraperitoneal surgery; history of congestive heart failure, insulin-dependent diabetes, and presence of chronic kidney disease (Creatinine > 2) [3]. Some guidelines and/or risk stratification calculators are available for preoperative screening for cardiovascular events including the Revised Cardiac Risk Index (RCRI) for preoperative risk assessment [4]. Other similar risk calculators include American College of Surgeons National Surgical Quality Improvement Program (NSQIP) risk prediction calculators and Bilimoria ACS surgical risk calculator.

In general, patient at low cardiovascular risk and/or undergoing low-risk, non-cardiac surgery may not need further preoperative screening or evaluation. Patients at high risk of complications, unknown or poor functional capacity (<4 METs) and/or undergoing high-risk surgery usually proceed to preoperative screening for Coronary Artery Disease (CAD) and subsequent revascularization and/or medical optimization prior to surgery if indicated [3, 5]. There are several modalities available to screening for CAD including exercise stress testing, Dobutamine stress testing, PET stress testing, Echo-stress testing, Nuclear Medicine stress testing, and Left Heart catheterization (LHC).

Of all the various modalities for CAD screening, exercise stress testing remains the preferred, firstline modality for CAD screening due to low cost and provision of additional information including patient's exercise capacity [6]. Although exercise stress testing is firstline, patients may have contraindication to exercise stress testing e.g., presence of Left Bundle Branch Block (LBBB); baseline ST segment depression/elevation; recent myocardial infarction; severe aortic stenosis; uncontrolled arrhythmia and other baseline electrocardiogram (EKG) abnormalities that may interfere with accurate interpretation of stress EKG [7]. Other factors that limit use of exercise stress testing include patient's inability to exercise on treadmill or chronotropic incompetence or heart block that may prevent patient from reaching acceptable heart rate – 85% of age-adjusted maximum heart rate [8].

When patients are unable to undergo exercise stress testing due to any of the above contraindications, other modalities including dobutamine stress testing, PET stress testing, echo-stress testing, nuclear medicine stress testing, or LHC can be used for CAD screening. Of all the available modalities, LHC is the most invasive but has benefit of al concomitant Percutaneous Intervention

(PCI) with balloon angioplasty, Bare Metal Stenting (BMS), or Drug-Eluting stenting (DES). Beyond the firstline, the exercise stress testing, the modality of choice varies across practices depending of availability at institution, expertise, cost, risk of contrast nephropathy or allergy, and patient preference.

The predictive accuracy of a screening modality refers to how accurate a screening tool is in determining if indeed there will be any ischemic postoperative complications. Two of the few ways to determine the predictive accuracy of a test include a Positive Predictive Value (PPV) and a Negative Predictive Value (NPV). A PPV is the probability that patients with a positive screening test truly have the disease while a NPV is the probability that patients with a negative screening test truly do not have the disease.

We evaluate, in this single-center study, the predictive accuracy of PET stress testing for ischemic cardiac complications in patients undergoing allogeneic liver transplantation due to end-stage liver disease (ESLD). Patients who had a negative PET stress testing for preoperative screening were monitored for up to 90 days postoperatively for any ischemic complications.

MATERIALS AND METHODS

A list of 94 patients who had allogeneic liver transplantation in a major tertiary center from 2009 to 2015 was reviewed to evaluate the predictive accuracy of PET stress testing for postoperative ischemic complications. Patients had varying preoperative cardiac screening including left heart catheterization, non-invasive treadmill stress test, nuclear medicine stress testing, PET stress testing, and dobutamine stress testing. To evaluate postoperative accuracy of PET stress testing, patients who had PET stress for their preoperative evaluation were selected from the entire pool of patients. A comprehensive chart review was done and pertinent data, e.g., preoperative cardiovascular risk factors and lab values were documented. Patients were also followed postoperatively and any adverse events attributable to cardiac ischemia were documented. Ischemic events monitored postoperatively include ST-elevation Myocardial Infarction (STEMI); Non-ST-elevation myocardial infarction (NSTEMI); new bundle branch block or similar ischemic complications. As shown in Figure 1, a total of 94 patients were evaluated for liver transplantation within the timeframe noted above. Out of 94 patients evaluated, only 43 patients went on to have liver transplantation during that time interval. Out of the 43 liver transplant patients, 31 patients had PET stress testing as their modality of choice for preoperative cardiac screening. Medical records of those 31 patients were reviewed and documented evidence of postoperative ischemic events including STEMI, NSTEMI, or heart block were recorded. Chart review was done at 30-day, 60-day, and 90-day postoperatively. In addition, patient demographics including age at evaluation, sex, cardiac

risk factors such as tobacco use, hypertension, diabetes, etiology of end stage liver disease, preoperative lab values including creatinine, total bilirubin, INR, and other pertinent data were recorded. These data are then used to determine predictive accuracy of PET stress testing for postoperative cardiac complications in this patient population. Data obtained were analyzed statistically.

RESULTS

In this tertiary institution, 94 patients with end-stage liver disease (ESLD) were evaluated for liver transplantation between 2009 and 2015. 51 patients did not have liver transplantation for various reasons including but not limited to poor social support, lack of availability of matched donor liver, lack of insurance, and medication non-adherence. 43 patients had liver transplantation. Out of 43 patients who had a liver transplant, 31 patients had a PET stress test preoperatively for cardiac ischemic evaluation as shown in Figure 1.

Preoperative and postoperative data for all 31 transplanted patients who had PET stress testing were analyzed. Table 1 shows baseline characteristics. A total of 31 patients: 25 (81%) men and 6 (19%) women with a mean age at transplantation of 55.3 y (range 38–67) were identified. Cardiac risk factors include diabetes 15 (48%), hypertension 16 (52%), and current/former tobacco use 17 (55%). Contributing factors to ESLD are chronic HCV infection 17 (55%), alcohol abuse 9 (29%), Non-alcoholic Steato-Hepatitis (NASH) 9 (29%); Primary Sclerosing Cholangitis (PSC)/Cholangiocarcinoma 1 (3%), sarcoidosis 1 (3%), and cryptogenic 1 (3%). Calculated MELD score for patients with preoperative labs ranged from 10.1 to 29.2.

All 31 patients had a PET stress testing for preoperative assessment. 29 (93%) had a negative stress test. Post liver transplantation, only 1 (3%) patient had third degree AV blocks attributable to ischemia at 60-day follow-up. Other notable postoperative complications include hypotension 5 (16%), acute renal failure 5 (16%), acute pulmonary edema 2 (6%), and congestive heart failure 4 (13%).

Using the data above, the NPV of PET stress testing was calculated. PET stress testing has a high NPV for postoperative acute coronary syndromes in this patient cohort, NPV of 96.5% (95% CI 96.22–96.88%).

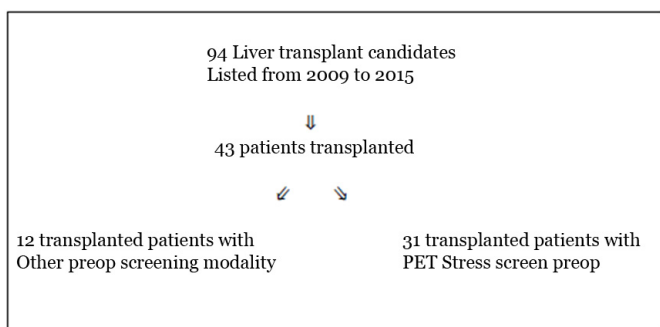

Figure 1: Selection of patient population for analysis.

Table 1: Baseline characteristics of liver transplant patients

Demographics	
Mean Age	55.3 y (range 38–67)
% Male	25 (81%)
Cardiac risk factors	
Hypertension	16 (52%)
Diabetes	15 (48%)
Tobacco use	17 (55%)
ESLD etiology/contributing factor	
HCV infection	17 (55%)
Alcohol abuse	9 (29%)
NASH	9 (19%)
PSC/cholangiocarcinoma	1 (3%)
Sarcoidosis	1 (3%)
Cryptogenic	1 (3%)

DISCUSSION

Perioperative ischemic cardiovascular and cerebrovascular accidents remain major contributor to morbidity and mortality following both cardiac and non-cardiac surgery. Patient at low cardiovascular risk and/or undergoing low-risk, non-cardiac surgery may not need further preoperative screening. Patients at high-risk of complications, unknown or poor functional capacity (<4 METs) and/or undergoing high-risk surgery usually proceed to preoperative screening for CAD and subsequent revascularization and/or medical optimization prior to surgery if indicated. For patients needing preoperative ischemic screening, there are several exercise, imaging, and invasive modalities available for CAD screening. These modalities include but not limited to Dobutamine stress testing, PET stress testing, echo-stress testing, Nuclear Medicine stress testing, and LHC. The test of choice often depends on availability at institution, expertise, cost, risk of contrast nephropathy or allergy, and patient preference.

We evaluate the predictive accuracy of PET stress testing in liver transplant patients at a major tertiary institution. We focus on monitoring patients for any cardiac postoperative complications that is attributable to ischemia in a cohort who had a negative PET stress testing preoperatively. Our endpoints include occurrence of STEMI, NSTEMI, infrahisian bundle block attributable to ischemia; and other manifestation of perioperative cardiac ischemia.

Of the 31 patients who had preoperative PET stress testing, 29 (93%) had a negative stress test while 2 (7%) had a positive test and went on to have pre-operative LHC. All 31 patients went on to have allogeneic liver transplantation. Post liver transplantation, only 1 (3%) out of 29 patients with preoperative negative PET stress test had ischemic complications within 90 days after surgery. The patient had third degree AV blocks attributable

to ischemia at 60-day follow-up. Other notable, non-ischemic postoperative complications include hypotension 5 (16%), acute renal failure 5 (16%), acute pulmonary edema 2 (6%), and congestive heart failure 4 (13%). Within this cohort, we found that PET stress testing has a high negative predictive value for postoperative acute coronary syndromes in liver transplant patients (NPV = 96.5%, 95% CI 96.22–96.88%), so therefore is an acceptable screening modality when there is a contraindication to or patient is unable to tolerate exercise stress testing. In review of literature [3–5], we found that non-invasive stress testing has a high negative predictive value and are very sensitive for screening of coronary artery disease in preoperative patients but we did not find literature specifically evaluating the negative predictive value, sensitivity and/or specificity of PET stress testing in preoperative patients. It is very noteworthy that our analysis is focused on limited patient population and is also limited by relatively small number of patients.

CONCLUSION

For patients at high-risk of complications, unknown or poor functional capacity (<4 METs) and/or undergoing high-risk surgery, exercise stress testing remains firstline for screening but when patients are unable to undergo exercise stress testing or have contraindications to exercise stress testing, PET stress testing is an acceptable alternative. PET stress testing has a high negative predictive value for postoperative acute coronary syndromes in liver transplant patients (NPV = 96.5%, 95% CI 96.22–96.88%).
